A simple method for automated equilibration detection in molecular simulations

Molecular simulations intended to compute equilibrium properties are often initiated from configurations that are highly atypical of equilibrium samples, a practice which can generate a distinct initial transient in mechanical observables computed from the simulation trajectory. Traditional practice in simulation data analysis recommends this initial portion be discarded to *equilibration*, but no simple, general, and automated procedure for this process exists. Here, we suggest a conceptually simple automated procedure that does not make strict assumptions about the distribution of the observable of interest, in which the equilibration time is chosen to maximize the number of effectively uncorrelated samples in the production timespan used to compute equilibrium averages. We present a simple Python reference implementation of this procedure, and demonstrate its utility on typical molecular simulation data.

Keywords: molecular dynamics (MD); Metropolis-Hastings; Monte Carlo (MC); Markov chain Monte Carlo (MCMC); equilibration; burn-in; timeseries analysis; statistical inefficiency; integrated autocorrelation time

14 15

Molecular simulations use Markov chain Monte Carlo (MCMC) techniques [1] to sample configurations x from an equilibrium distribution $\pi(x)$, either exactly (using Monte Carlo methods such as Metropolis-Hastings) or approximately (using molecular dynamics integrators without Metropolization) [2].

Due to the sensitivity of the equilibrium probability density $\pi(x)$ to small perturbations in configuration x and the difficulty of producing sufficiently good guesses of typical equilibrium configurations $x \sim \pi(x)$, these molecular simulations are often started from highly atypical initial conditions. For example, simulations of biopolymers might be initiated from a fully extended conformation unrepresentative of behavior in solution, or a geometry derived from a fit 33 to diffraction data collected from a cryocooled crystal; solvated systems may be prepared by periodically replicating small solvent box equilibrated under different conditions, yielding atypical densities and solvent structure; liquid mixtures or lipid bilayers may be constructed by using methods that fulfill spatial constraints (e.g. PackMol [3]) but create locally aytpical geometries, requiring long simulation times to relax to typical configurations.

As a result, traditional practice in molecular simulation has recommended some initial portion of the trajectory be discarded to *equilibration* (also called *burn-in*¹ in the MCMC literature [4]). While the process of discarding initial samples is strictly unnecessary for the time-average of quantities of interest to eventually converge to the desired expectations [5], this nevertheless often allows the practitioner to avoid what may be impractically long run times to eliminate the bias in computed properties in finite-length simulations

50 induced by atypical initial starting conditions. It is worth 51 noting that a similar procedure is not a practice universally 52 recommended by statisticians when sampling from poste-53 rior distributions in statistical inference [4]; the differences 54 in complexity of probability densities typically encountered 55 in statistics and molecular simulation may explain the dif-56 ference in historical practice.

As a motivating example, consider the computation of the sa average density of liquid argon under a given set of reduced 59 temperature and pressure conditions shown in Figure 1. To 60 initiate the simulation, an initial dense liquid geometry at reduced density $\rho^* \equiv \rho \sigma^3 = 0.960$ was prepared and sub-62 jected to local energy minimization. The upper panel of Figure 1 depicts the average relaxation behavior of simulations 64 initiated from the same configuration with different random 65 initial velocities and integrator random number seeds (see 66 Simulation Details). The average of 500 realizations of this 67 process shows a characteristic relaxation away from the ini-68 tial density toward the equilibrium density (Figure 1, upper panel, black line). As a result, the expectation of the running 70 average of the density significantly deviates from the true 71 expectation (Figure 1, lower panel, dashed line). This effect 12 leads to significantly biased estimates of the expectation un-73 less simulations are sufficiently long to eliminate starting ₇₄ point dependent bias, which takes a surprisingly long \sim 30 ₇₅ ns in this example. Note that this bias is present even in ₇₆ the average of many realizations because the same atypical 77 starting condition is used for every realization of this simu-78 lation process.

To develop an automatic approach to eliminating this bias, we take motivation from the concept of *reverse cumulative averaging* from Yang et al. [6], in which the trajectory statistics over the production region of the trajectory are examined for different choices of the end of the discarded equilibration region to determine the optimal production region to use for computing expectations and other statistical properties. We begin by first formalizing our objectives mathematically.

¹ The term *burn-in* comes from the field of electronics, in which a short "burn-in" period is used to ensure that a device is free of faulty components—which often fail quickly—and is operating normally [4].

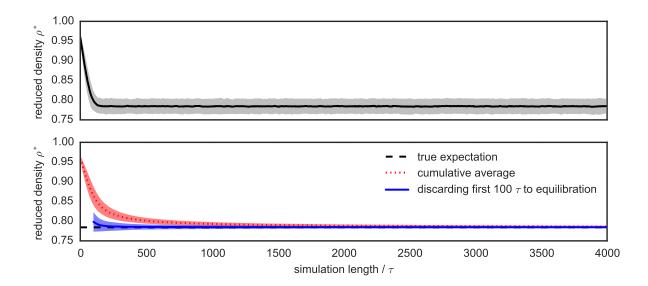

FIG. 1. Illustration of the motivation for discarding data to equilibration. To illustrate the bias in expectations induced by relaxation away from initial conditions, 500 replicates of a simulation of liquid argon were initiated from the same energy-minimized initial configuration constructed with initial reduced density $\rho^* \equiv \rho \sigma^3 = 0.960$ but different random number seeds for stochastic integration. **Top:** The average of the reduced density (black line) over the replicates relaxes to the region of typical equilibrium densities over the first $\sim 90~\tau$ of simulation time, where τ is a natural time unit (see *Simulation Details*). **Bottom:** If the average density is estimated by a cumulative average from the beginning of the simulation (red dotted line), the estimate will be heavily biased by the atypical starting density even beyond $1000~\tau$. Discarding even a small amount of initial data—in this case 500 initial samples—results in a cumulative average estimate that converges to the true average (black dashed line) much more rapidly. Shaded regions denote 95% confidence intervals.

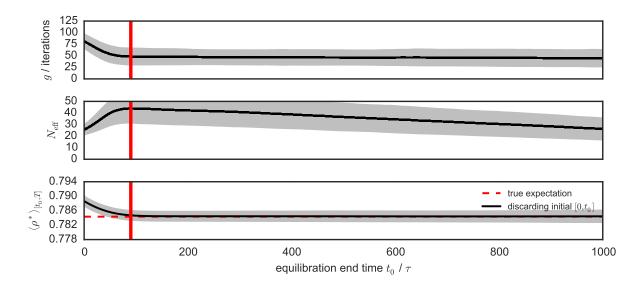

FIG. 2. Statistical inefficiency, number of uncorrelated samples, and bias for different equilibration times. Trajectories of length $T=2000~\tau$ for the argon system described in Figure 1 were analyzed as a function of equilibration time choice t_0 . Averages over all 500 replicate simulations (all starting from the same initial conditions) are shown as dark lines, with shaded lines showing standard deviation of estimates among replicates. **Top:** The statistical inefficiency g as a function of equilibration time choice t_0 is initially very large, but diminishes rapidly after the system has relaxed to equilibrium. **Middle:** The number of effectively uncorrelated samples $N_{\rm eff} = (T-t_0+1)/g$ shows a maximum at $t_0 \sim 90~\tau$ (red vertical lines), suggesting the system has equilibrated by this time. **Bottom:** The cumulative average density $\langle \rho^* \rangle$ computed over the span $[t_0,T]$ shows that the bias (deviation from the true estimate, shown as red dashed lines) is minimized for choices of $t_0 \geq 90~\tau$. The standard deviation among replicates (shaded region) grows with t_0 because fewer data are included in the estimate. The choice of optimal t_0 that maximizes $N_{\rm eff}$ (red vertical line) strikes a good balance between bias and variance. The true estimate (red dashed lines) is computed from averaging over the range $[5~000,10~000]~\tau$ over all 500 replicates.

Consider T successively sampled configurations x_t from a molecular simulation, with $t=1,\ldots,T$, initiated from x_0 . We presume we are interested in computing the expectation

$$\langle A \rangle \equiv \int dx \, A(x) \, \pi(x)$$
 (1)

 $_{^{92}}$ of a mechanical property of interest A(x). For convenience, $_{^{93}}$ we will refer to the timeseries $a_t\equiv A(x_t)$, with $t\in[1,T]$. $_{^{94}}$ The estimator $\hat{A}\approx\langle A\rangle$ constructed from the entire dataset $_{^{95}}$ is given by

$$\hat{A}_{[1,T]} \equiv \frac{1}{T} \sum_{t=1}^{T} a_t. \tag{2}$$

 $^{_{96}}$ While $\lim_{T\to\infty}\hat{A}_{[1,T]}=\langle A\rangle$ for an infinitely long simula- $^{_{97}}$ tion², the bias in $\hat{A}_{[1,T]}$ may be significant in a simulation of $^{_{98}}$ finite length T.

By discarding samples $t < t_0$ to equilibration, we hope to exclude the initial transient from our sample average, and provide a less biased estimate of $\langle A \rangle$,

$$\hat{A}_{[t_0,T]} \equiv \frac{1}{T - t_0 + 1} \sum_{t=t_0}^{T} a_t.$$
 (3)

We can quantify the overall error in an estimator $\hat{A}_{[t_0,T]}$ in a sample average that starts at x_0 and excludes samples where $t < t_0$ by the expected error $\delta^2 \hat{A}_{[t_0,T]}$,

$$\delta^2 \hat{A}_{[t_0,T]} \equiv E_{x_0} \left[\left(\hat{A}_{[t_0,T]} - \langle A \rangle \right)^2 \right] \tag{4}$$

where $E_{x_0}[\cdot]$ denotes the expectation over independent realizations of the specific simulation process initiated from configuration x_0 , but with different velocities and random number seeds.

We can rewrite the expected error $\delta^2\hat{A}$ by separating it into two components:

$$\delta^{2} \hat{A}_{[t_{0},T]} = E_{x_{0}} \left[\left(\hat{A}_{[t_{0},T]} - E_{x_{0}} [\hat{A}_{[t_{0},T]}] \right)^{2} \right] + \left(E_{x_{0}} [\hat{A}_{[t_{0},T]}] - \langle A \rangle \right)^{2}$$
 (5)

The first term denotes the variance in the estimator \hat{A} ,

$$\operatorname{var}_{x_0}(\hat{A}_{[t_0,T]}) \equiv E_{x_0} \left[\hat{A}_{[t_0,T]} - E_{x_0} [\hat{A}_{[t_0,T]}] \right]^2$$
 (6)

 $_{\mbox{\scriptsize 112}}$ while the second term denotes the contribution from the $_{\mbox{\scriptsize 113}}$ squared bias,

$$bias_{x_0}^2(\hat{A}_{[t_0,T]}) \equiv \left(E_{x_0}[\hat{A}_{[t_0,T]}] - \langle A \rangle\right)^2$$
 (7)

With increasing equilibration time t_0 , bias is reduced, but the variance—the contribution to error due to random variation from having a finite number of uncorrelated samples—will increase because less data is included in the estimate. This can be seen in the bottom panel of Figure 2, where the shaded region (95% confidence interval of the mean) increases in width with increasing equilibration time t_0 .

To examine the tradeoff between bias and variance explicitly, Figure 3 plots the bias and variance (here, shown as standard error) contributions against each other as a function of t_0 (denoted by color) as computed from statistics over all 500 replicates. At $t_0=0$, the bias is large but variance is minimized. With increasing t_0 , bias is eventually eliminated but then variance rapidly grows as fewer uncorrelated samples are included in the estimate. There is a clear optimal choice at $t_0\sim 90~\tau$ that minimizes variance while also effectively eliminating bias (where τ is a natural time unit—see size to simulation Details).

SELECTING THE EQUILIBRATION TIME

Is there a simple approach to choosing an optimal equilibration time t_0 that provides a significantly improved estimate $\hat{A}_{[t_0,T]}$, even when we do not have access to multiple realizations? At worst, we hope that such a procedure would at least give some improvement over the naive estimate, such that $\delta^2\hat{A}_{[t_0,T]}<\delta^2\hat{A}_{[0,T]}$; at best, we hope that we can achieve a reasonable bias-variance tradeoff close to the optimal point identified in Figure 3 that minimizes bias without greatly increasing variance. We remark that, for cases in which the simulation is not long enough to reach equilibrium, no choice of t_0 will eliminate bias completely; the best we can hope for is to minimize this bias.

While automated methods for selecting the equilibration time t_0 have been proposed, these approaches have shortcomings that have greatly limited their use. The reverse cumulative averaging (RCA) method proposed by Yang et al. [6], for example, uses a statistical test for normality to determine the point before which which the observable time-152 series deviates from normality when examining the timeseries in reverse. While this concept may be reasonable for experimental data, where measurements often represent the sum of many random variables such that the central limit theorem's guarantee of asymptotic normality ensures the distribution of the observable will be approximately normal, there is no such guarantee that instantaneous measurements of a simulation property of interest will be normally distributed. In fact, many properties will be decidedly 161 non-normal. For a biomolecule such as a protein, for example, the radius of gyration, end-to-end distance, and torsion angles sampled during a simulation will all be highly non-164 normal. Instead, we require a method that makes no assumptions about the nature of the distribution of the prop-166 erty under study.

 $^{^2}$ We note that this equality only holds for simulation schemes that sample from the true equilibrium density $\pi(x)$, such as Metropolis-Hastings Monte Carlo or Metropolized dynamical integration schemes such as hybrid Monte Carlo (HMC). Molecular dynamics simulations utilizing finite timestep integration without Metropolization will produce averages that may deviate from the true expectation $\langle A \rangle$ [2].

AUTOCORRELATION ANALYSIS

167

168

The set of successively sampled configurations $\{x_t\}$ and their corresponding observables $\{a_t\}$ compose a correlated timeseries of observations. To estimate the statistical error or uncertainty in a stationary timeseries free of bias, we must be able to quantify the *effective number of uncorrelated samples* present in the dataset. This is usually accomplished through computation of the *statistical inefficiency g*, which quantifies the number of correlated timeseries samples needed to produce a single effectively uncorrelated sample of the observable of interest. While these concepts are well-established for the analysis of both Monte Carlo and molecular dynamics simulations [7–10], we review them here for the sake of clarity.

For a given equilibration time choice t_0 , the statistical un- certainty in our estimator $\hat{A}_{[t_0,T]}$ can be written as,

$$\delta^{2} \hat{A}_{[t_{0},T]} \equiv E_{x_{0}} \left[\left(\hat{A}_{[t_{0},T]} - \langle \hat{A} \rangle \right)^{2} \right]$$

$$= E_{x_{0}} \left[\hat{A}_{[t_{0},T]}^{2} \right] - E_{x_{0}} \left[\hat{A}_{[t_{0},T]} \right]^{2}$$

$$= \frac{1}{T_{t_{0}}^{2}} \sum_{t,t'=t_{0}}^{T} \left\{ E_{x_{0}} \left[a_{t} a_{t'} \right] - E_{x_{0}} \left[a_{t} \right] E_{x_{0}} \left[a_{t'} \right] \right\}$$

$$= \frac{1}{T_{t_{0}}^{2}} \sum_{t=t_{0}}^{T} \left\{ E_{x_{0}} \left[a_{t}^{2} \right] - E_{x_{0}} \left[a_{t} \right]^{2} \right\}$$

$$+ \frac{1}{T_{t_{0}}^{2}} \sum_{t\neq t'=t_{0}}^{T} \left\{ E_{x_{0}} \left[a_{t} a_{t'} \right] - E_{x_{0}} \left[a_{t} \right] E_{x_{0}} \left[a_{t'} \right] \right\},$$

$$(8)$$

 $_{^{183}}$ where $T_{t_0}\equiv T-t_0+1$, the number of correlated samples $_{^{184}}$ in the timeseries $\{a_t\}_{t_0}^T$. In the last step, we have split the double-sum into two separate sums—a term capturing the variance in the observations a_t , and a remaining term capturing the correlation between observations.

188 If t_0 is sufficiently large for the initial bias to be eliminated, the remaining timeseries $\{a_t\}_{t_0}^T$ will obey the properties of both stationarity and time-reversibility, allowing us to write,

$$\delta^{2} \hat{A}_{[t_{0},T]}^{\text{equil}} = \frac{1}{T_{t_{0}}} \left[\langle a_{t}^{2} \rangle - \langle a_{t} \rangle^{2} \right]$$

$$+ \frac{2}{T_{t_{0}}} \sum_{n=1}^{T-t_{0}} \left(\frac{T_{t_{0}} - n}{T_{t_{0}}} \right) \left[\langle a_{t} a_{t+n} \rangle - \langle a_{t} \rangle \langle a_{t+n} \rangle \right]$$

$$\equiv \frac{\sigma_{t_{0}}^{2}}{T_{t_{0}}} (1 + 2\tau_{t_{0}}) = \frac{\sigma_{t_{0}}^{2}}{T_{t_{0}}/g_{t_{0}}}, \tag{9}$$

 $_{^{191}}$ where the variance σ^2 , statistical inefficiency g , and integrated autocorrelation time τ (in units of the sampling interval) are given by

$$\sigma^2 \equiv \langle a_t^2 \rangle - \langle a_t \rangle^2, \tag{10}$$

$$\tau \equiv \sum_{t=1}^{T-1} \left(1 - \frac{t}{T} \right) C_t, \tag{11}$$

$$g \equiv 1 + 2\tau,\tag{12}$$

 $_{\scriptscriptstyle{194}}$ with the discrete-time normalized fluctuation autocorrela- $_{\scriptscriptstyle{195}}$ tion function C_t defined as

$$C_t \equiv \frac{\langle a_n a_{n+t} \rangle - \langle a_n \rangle^2}{\langle a_n^2 \rangle - \langle a_n \rangle^2}.$$
 (13)

 196 In practice, it is difficult to estimate C_t for $t\sim T$, due to 197 growth in the statistical error, so common estimators of g 198 make use of several additional properties of C_t to provide 199 useful estimates (see Practical Computation of Statistical In- 200 efficiencies).

The t_0 subscript for the variance σ^2 , the integrated auto-correlation time τ , and the statistical inefficiency t_0 mean that these quantities are only estimated over the production portion of the timeseries, $\{a_t\}_{t=t_0}^T$. Since we assumed that the bias was eliminated by judicious choice of the equilibration time t_0 , this estimate of the statistical error will be poor for choices of t_0 that are too small.

THE ESSENTIAL IDEA

Suppose we choose some arbitrary time t_0 and discard all samples $t\in[0,t_0)$ to equilibration, keeping $[t_0,T]$ as the dataset to analyze. How much data remains? We can determine this by computing the statistical inefficiency g_{t_0} for the interval $[t_0,T]$, and computing the effective number of uncorrelated samples $N_{\rm eff}(t_0)\equiv (T-t_0+1)/g_{t_0}$. If we start at $t_0\equiv T$ and move t_0 to earlier and earlier points in time, we expect that the effective number of uncorrelated samples $N_{\rm eff}(t_0)$ will continue to grow until we start to include the highly atypical initial data. At that point, the integrated autocorrelation time τ (and hence the statistical inefficiency g) will greatly increase (a phenomenon observed earlier, e.g. Figure 2 of [6]). As a result, the effective number of samples $N_{\rm eff}$ will start to plummet.

Figure 2 demonstrates this behavior for the liquid argon system described above, using averages of the statistical inefficiency g_{t_0} and $N_{\rm eff}(t_0)$ computed over 500 independent replicate trajectories. At short t_0 , the average statistical inefficiency g (Figure 2, top panel) is large due to the contribution from slow relaxation from atypical initial conditions, while at long t_0 the statistical inefficiency estimate is much shorter and nearly constant of a large span of time origins. As a result, the average effective number of uncorrelated samples $N_{\rm eff}$ (Figure 2, middle panel) has a peak at $t_0\sim 90~\tau$ (Figure 2, vertical red lines). The effect on bias in the estimated average reduced density $\langle \rho^* \rangle$ (Figure 2, bottom panel) is striking—the bias is essentially eliminated for the choice of equilibration time t_0 that maximizes the number of uncorrelated samples $N_{\rm eff}$.

This suggests an alluringly simple algorithm for identifying in- the optimal equilibration time—pick the t_0 which maximizes the number of uncorrelated samples $N_{\rm eff}$ in the time- series $\{a_t\}_{t_0}^T$ for the quantity of interest A(x):

$$t_0^{\text{opt}} = \operatorname*{argmax}_{t_0} N_{\text{eff}}(t_0)$$

$$= \operatorname*{argmax}_{t_0} \frac{T - t_0 + 1}{g_{t_0}}$$

$$(14)$$

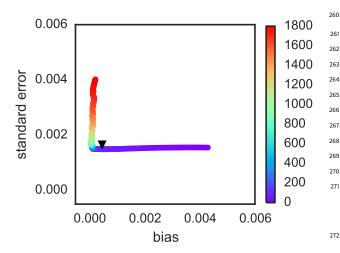

FIG. 3. Bias-variance tradeoff for fixed equilibration time versus automatic equilibration time selection. Trajectories of length $T=2000\tau$ for the argon system described in Figure 1 were analyzed as a function of equilibration time choice t_0 , with colors denoting the value of t_0 (in units of τ) corresponding to each plotted point. Using 500 replicate simulations, the average bias (average deviation from true expectation) and standard deviation (random variation from replicate to replicate) were computed as a function of a prespecified fixed equilibration time t_0 , with colors running from violet (0 au) to red (1800 au). As is readily discerned, the 284 there is no need to store full configurations x_t —and postbias for small t_0 is initially large, but minimized for larger t_0 . By contrast, the standard error (a measure of variance, estimated here 286 which we have provided a convenient Python reference imby standard deviation among replicates) grows as t_0 grows above a certain critical time (here, $\sim 90\,\tau$). If the t_0 that maximizes $N_{\rm eff}$ is instead chosen individually for each trajectory based on that trajectory's estimates of statistical inefficiency $g_{\left[t_0,T\right]}$, the resulting biasvariance tradeoff (black triangle) does an excellent job minimizing bias and variance simultaneously, comparable to what is possible for a choice of equilibration time t_0 based on knowledge of the true bias and variance among many replicate estimates.

Bias-variance tradeoff. How will the simple strategy of selecting the equilibration time t_0 using Eq 14 work for cases where we do not know the statistical inefficiency g as a function of the equilibration time t_0 precisely? When all that is available is a single simulation, our best estimate of g_{t_0} is derived from that simulation alone over the span $[t_0, T]$ —will this affect the quality of our estimate of equilibration time? mpirically, this does not appear to be the case—the black triangle in Figure 3 shows the bias and variance contributions to the error for estimates computed over the 500 replicates where t_0 is individually determined from each simulation using this simple scheme based on selecting t_0 to maximize $N_{
m eff}$ for each individual realization. Despite not having knowledge about multiple realizations, this strategy effec-₂₅₇ bias without increasing variance.

Overall RMS error. How well does this strategy perform in terms of decreasing the *overall* error $\delta \hat{A}_{[t_0,T]}$ compared $\delta \hat{A}_{[0,T]}$? Figure 4 compares the expected standard er- $_{261}$ ror (denoted $\delta\hat{A}$) as a function of a fixed initial equilibration $time t_0$ (black line with shaded region denoting 95% confi- $_{263}$ dence interval) with the strategy of selecting t_0 to maximize $_{
m 264}$ $N_{
m eff}$ for each realization (red line with shaded region de-265 noting 95% confidence interval). While the minimum error $_{266}$ for the fixed- t_0 strategy (0.00154 \pm 0.00005) is achieved at $_{267}$ 90~ au—a fact that could only be determined from knowledge $_{268}$ of multiple realizations—the simple strategy of selecting t_0 using Eq. 14 achieves a minimum error of 0.00171 ± 0.00006 , only 11% worse (compared to errors of 0.00456 ± 0.00007 , or 271 296% worse, should no data have been discarded).

DISCUSSION

The scheme described here—in which the equilibration t_0 time t_0 is computed using Eq. 14 as the choice that maxi-275 mizes the number of uncorrelated samples in the production region $[t_0, T]$ —is both conceptually and computationally straightforward. It provides an approach to determining the optimal amount of initial data to discard to equili-279 bration in order to minimize variance while also minimizing 280 initial bias, and does this without employing statistical tests ²⁸¹ that require generally unsatisfiable assumptions of normal-282 ity of the observable of interest. All that is needed is to save the timeseries $\{a_t\}_1^T$ of the observable A(x) of interest— ₂₈₅ process this dataset with a simple analysis procedure, for plementation (see Simulation Details). As we have seen, this scheme empirically appears to select a practical compro-289 mise between bias and variance even when the statistical inefficiency g is estimated directly from the trajectory using 291 Eq. 12.

A word of caution is necessary. One can certainly envision pathological scenarios where this algorithm for selecting an 294 optimal equilibration time will break down. In cases where the simulation is not long enough to reach equilibrium—let alone collect many uncorrelated samples from it—no choice of equilibration time will bestow upon the experimenter the ability to produce an unbiased estimate of the true expectation. Similarly, in cases where insufficient data is available for the statistical inefficiency to be estimated well, this algorithm is expected to perform poorly. However, in these 302 cases, the data itself should be suspect if the trajectory is not 303 at least an order of magnitude longer than the minimum estimated autocorrelation time.

SIMULATION DETAILS

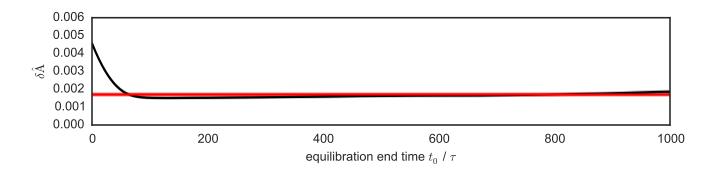

FIG. 4. RMS error for fixed equilibration time versus automatic equilibration time selection. Trajectories of length $T=2000\tau$ for the argon system described in Figure 1 were analyzed as a function of fixed equilibration time choice t_0 . Using 500 replicate simulations, the root-mean-squared (RMS) error (Eq. 4) was computed (black line) along with 95% confidence interval (gray shading). The RMS error is minimized for fixed equilibration time choices in the range 90–200 τ . If the t_0 that maximizes $N_{\rm eff}$ is instead chosen individually for each trajectory based on that trajectory's estimated statistical inefficiency $g_{[t_0,T]}$ using Eq. 14, the resulting RMS error (red line, 95% confidence interval shown as red shading) is quite close to the minimum RMS error achieved from any particular fixed choice of equilibration time to, suggesting that this simple automated approach to selecting t_0 achieves close to optimal performance.

versions used here, run the simulations, analyze data, and generate plots-along with the simulation data itself and scripts for generating figures—are available on GitHub³.

To model liquid argon, the LennardJonesFluid model system in the openmmtools package⁴ was used with parameters appropriate for liquid argon ($\sigma = 3.4 \text{ Å}, \epsilon = 0.238$ kcal/mol). All results are reported in reduced (dimensionless) units. A cubic switching function was employed, with the potential gently switched to zero over $r \in [\sigma, 3\sigma]$, and a long-range isotropic dispersion correction accounting for this switching behavior used to include neglected contributions. Simulations were performed using a periodic box of $_{ exttt{321}}$ $N\,=\,500$ atoms at reduced temperature $T^*\,\equiv\,k_BT/\epsilon\,=\,$ $_{ ext{322}}$ 0.850 and reduced pressure $p^* \equiv p\sigma^3/\epsilon = 1.266$ using a Langevin integrator [12] with timestep $\Delta t = 0.01 au$ and collision rate $\nu = \tau^{-1}$, with characteristic oscillation timescale $=\sqrt{mr_0^2/72\epsilon}$ and $r_0=2^{1/6}\sigma$ [13]. All times are reported $_{326}$ in multiples of the characteristic timescale au. A molecu-327 lar scaling Metropolis Monte Carlo barostat with Gaussian simulation volume change proposal moves attempted every τ (100 timesteps), using an adaptive algorithm that adjusts the proposal width during the initial part of the simulation [11]. Densities were recorded every τ (100 timesteps). The true expectation $\langle \rho^* \rangle$ was estimated from the sample average over all 500 realizations over [5000,10000] τ .

The automated equilibration detection scheme is also 335 available in the timeseries module of the pymbar package as detectEquilibration(), and can be accessed us-337 ing the following code:

from pymbar.timeseries import detectEquilibration # determine equilibrated region [t0, g, Neff_max] = detectEquilibration(A_t) # discard initial samples to equilibration $A_t = A_t[t0:]$

PRACTICAL COMPUTATION OF STATISTICAL INEFFICIENCIES

The robust computation of the statistical inefficiency g(defined by Eq. 12) for a finite timeseries $a_t, t = 0, \dots, T$ 341 deserves some comment. There are, in fact, a variety of $_{342}$ schemes for estimating g described in the literature, and their behaviors for finite datasets may differ, leading to dif- $_{344}$ ferent estimates of the equilibration time t_0 using the algo-345 rithm of Eq. 14.

The main issue is that a straightforward approach to es-347 timating the statistical inefficiency using Eqs. 11-13 in which the expectations are simply replaced with sample estimates causes the statistical error in the estimated correlation func- $_{ exttt{350}}$ tion C_t to grow with t in a manner that allows this error to quickly overwhelm the sum of Eq. 11. As a result, a number of 352 alternative schemes—generally based on controlling the er- $_{353}$ ror in the estimated C_t or truncating the sum of Eq. 11 when the error grows too large—have been proposed.

For stationary, irreducible, reversible Markov chains, $_{\mbox{\tiny 356}}$ Geyer observed that a function $\Gamma_k \, \equiv \, \gamma_{2k} \, + \, \gamma_{2k+1}$ of the $_{ exttt{357}}$ unnormalized fluctuation autocorrelation function γ_t \equiv $\langle a_i a_{i+t} \rangle - \langle a_i \rangle^2$ has a number of pleasant properties (The-359 orem 3.1 of [14]): It is strictly positive, strictly decreasing, and strictly convex. Some or all of these properties can be exploited to define a family of estimators called *initial* se-362 quence methods (see Section 3.3 of [14] and Section 1.10.2 http://github.com/choderalab/automatic-equilibration-detegatof [4]), of which the initial convex sequence (ICS) estimator is 364 generally agreed to be optimal, if somewhat more complex
